Poristic Triangles of the Arbelos

Antonio Gutierrez, Hiroshi Okumura and Hussein Tahir

Abstract. The arbelos is associated with poristic triangles whose circumcircle is the outer circle forming the arbelos. The triangles give infinitely many sextuplets of Archimedean circles and their intouch triangles share the same nine-point circle, which is also Archimedean and has center on the Schoch line.

1. Introduction

An arbelos is one of the two congruent areas surrounded by three mutually touching circles with collinear centers in the plane in a restricted sense. Circles having common radius equal to the half the harmonic mean of the radii of the two inner circles are said to be Archimedean, which are one of the main topics on the arbelos.

In this article, we show that the arbelos can naturally be associated with a set of poristic triangles, whose circumcircle is the outer circle forming the arbelos. The triangles give two families of infinitely many sextuplets of Archimedean circles. The intouch triangles of the poristic triangles share the same nine-point circle, which is also Archimedean and has center at the point of intersection of the Schoch line and the line passing through the centers of the circles forming the arbelos. Some special cases are considered.

2. Base Triangle of the Arbelos

In this section we construct a special triangle of the arbelos. For two points $P$ and $Q$, $P(Q)$ denotes the circle with center $P$ passing through $Q$, and $(PQ)$ denotes the circle with a diameter $PQ$. The center of a circle $\delta$ is denoted by $O_\delta$.

Let $O$ be a point on the segment $AB$, and let $\alpha = (AO)$, $\beta = (BO)$ and $\gamma = (AB)$. The configuration of the three circles is denoted by $(\alpha, \beta, \gamma)$ and called an arbelos. Let $a = |AO|/2$ and $b = |BO|/2$. Circles of radius $ab/(a+b)$ are called Archimedean circles of $(\alpha, \beta, \gamma)$, or said to be Archimedean with

Keywords and phrases: arbelos, Archimedean circles, nine-point circle, Schoch line, poristic triangles

(2010)Mathematics Subject Classification: 51M04, 51N20
respect to \((\alpha, \beta, \gamma)\), and the common radius is denoted by \(r_A\). We use a rectangular coordinate system with origin \(O\) such that the points \(A\) and \(B\) have coordinates \((2a, 0)\) and \((-2b, 0)\) respectively. The radical axis of \(\alpha\) and \(\beta\) is called the axis of the arbelos, which overlaps with the \(y\)-axis. The point of intersection of the axis and \(\gamma\) lying in the region \(y > 0\) is denote by \(I\). It has coordinates \((0, 2\sqrt{ab})\). The external common tangent of \(\alpha\) and \(\beta\) touching the two circles in the region \(y < 0\) is expressed by the equation [8]:

\[
(a - b)x + 2\sqrt{ab}y + 2ab = 0.
\]

Let \(J\) and \(K\) be the points of intersection of \(\gamma\) and this tangent, where \(J\) is closer to \(B\) than \(K\) (see Figure 1). We call \(IJK\) the base triangle of \((\alpha, \beta, \gamma)\). Let \(g = a + b\), \(u = a - b\), \(w = a^2 + b^2\) and \(v = \sqrt{w + ab}\). The points \(J\) and \(K\) have coordinates

\[
\left(\frac{2r_A(u - 2v)}{g}, -\frac{2\sqrt{ab}(w - uv)}{g^2}\right) \quad \text{and} \quad \left(\frac{2r_A(u + 2v)}{g}, -\frac{2\sqrt{ab}(w + uv)}{g^2}\right),
\]

respectively. Therefore the lines \(IJ\) and \(KI\) are expressed by the equations

\[
vx - \sqrt{ab}y + 2ab = 0 \quad \text{and} \quad -vx - \sqrt{ab}y + 2ab = 0,
\]

respectively. The equations show that the lines \(IJ\) and \(KI\) are symmetric in the axis. They also show that each of the distances from \(O\) to \(IJ\) and from \(O\) to \(KI\) is \(2ab/\sqrt{w^2 + ab} = 2r_A\). On the other hand, the distance between \(O\) and \(JK\) also equals \(2r_A\) [2], which is also obtained from (1). Therefore we get:

\textbf{Theorem 2.1.} \textit{The base triangle }\(IJK\text{ has incircle of radius }2r_A\text{ with center }O\).

3. \textsc{Poristic triangles of the arbelos}

Let \(\zeta\) be the incircle of the triangle \(IJK\). Since \(IJK\) has circumcircle \(\gamma\) and incircle \(\zeta\), there is a continuous family of triangles with the same circumcircle and incircle by the Poncelet closure theorem. We call the triangles the poristic triangles of \((\alpha, \beta, \gamma)\). In this section we show that each of the poristic triangles of \((\alpha, \beta, \gamma)\) gives several Archimedean circles and the intouch triangles of the poristic triangles share the same nine-point circle.
Let $EFG$ be a poristic triangle of $(\alpha, \beta, \gamma)$, and let $E'F'G'$ be its intouch triangle, where $E'$, $F'$ and $G'$ lie on the segments $FG$, $GE$ and $EF$, respectively (see Figure 2). Let $E_m$ be the midpoint of $EO$. The points $F_m$ and $G_m$ are defined similarly.

**Theorem 3.1.** The following statements hold.

(i) The circles $(EO)$ and $(FO)$ share the chord $G'O$, and the circle $(G'O)$ is Archimedean and is the inverse of the line $EF$ in the circle $\zeta$ for the points $E$, $F$ and $G$. Similar facts are true for the points $E'$, $F$ and $G$ and for $E$, $F'$ and $G$.

(ii) The circle with center $E_m$ touching the sides $GE$ and $EF$ is Archimedean. Similar facts are true for the points $F_m$ and $G_m$ and the corresponding sides of the triangle $EFG$.

(iii) The points $E_m$, $F_m$ and $G_m$ lie on the circle $(O_aO_\beta)$.

**Proof.** The part (i) is obvious. The homothety with center $E$ and ratio $1/2$ carries the circle $\zeta$ and the point $O$ into the Archimedean circle touching $EF$ and $GE$ and the point $E_m$, respectively. This proves (ii). The homothety with center $O$ and ratio $1/2$ carries $\gamma$ and $E$ into the circle $(O_aO_\beta)$ and $E_m$. This proves (iii).

![Figure 2.](image)

We get a sextuplet of Archimedean circles from a poristic triangle of $(\alpha, \beta, \gamma)$ by the theorem. Therefore we get infinitely many sextuplets of Archimedean circles. For a triangle $\Delta$ with inradius $2r$, we can construct an arbelos with Archimedean circles of radius $r$ and a poristic triangle $\Delta$.

**Corollary 3.2.** For a triangle $\Delta$ with inradius $2r$ and incenter $O'$, let $\gamma'$ be the circumcircle of $\Delta$. If the line $O'O_{\gamma'}$ intersects $\gamma'$ at points $A'$ and $B'$, let $\alpha = (A'O')$ and $\beta' = (B'O')$. Then $(\alpha', \beta', \gamma')$ is an arbelos with Archimedean circles of radius $r$ and a poristic triangle $\Delta$.

Let $s = -r_{\Delta}/g$. The line expressed by the equation $x = s$ is called the Schoch line of $(\alpha, \beta, \gamma)$ [9]. Let $E''$ be the point of intersection of $(F'O)$ and
(G′O) different from O. The points F′′ and G′′ are defined similarly. Let ε be the circle passing through E′′, F′′ and G′′ (see Figure 3). Then ε is Archimedean with respect to (α, β, γ) [4].

**Theorem 3.3.** The following statements are true.

(i) The point E′′ is the midpoint of F′G′ and lies on the segment EO. Similar facts are true for the points F′′ and G′′.

(ii) The circle ε is the inverse of γ in the circle ζ and is the nine-point circle of the triangle E′G′F′. The center of ε coincides with the point of intersection of the Schoch line and AB.

**Proof.** The line F′G′ is the inverse of the circle (EO) in ζ, and EG′OF′ is a kite. Hence E′′ is the midpoint of F′G′. This proves (i). Since E′′ is the inverse of E in ζ and similar facts are true for F and F′′ and for G and G′′, the circle ε is the inverse of γ in ζ. The inverses of A and B in ζ are the endpoints of a diameter of ε and have x-coordinates 2r₂A/a and −2r₂A/b. Hence the center of ε has x-coordinate r₂A/a − r₂A/b = s. The rest of (ii) is obvious.

**Corollary 3.4.** The intouch triangles of the poristic triangles of (α, β, γ) share the same Archimedean nine-point circle ε. In general, the intouch triangles of the poristic triangles with the same circumcircle and incircle of a triangle share the same nine-point circle.
4. An arbelos derived from Dao’s result

From the arbelos \((\alpha, \beta, \gamma)\) we can construct another arbelos, which shares Archimedean circles with \((\alpha, \beta, \gamma)\). Suppose that the external common tangent of \(\alpha\) and \(\beta\) touching the two circles in the region \(y > 0\) intersects \(\gamma\) at points \(S\) and \(T\) (see Figure 4). Let \(U\) be the point of intersection of the tangents of \(\gamma\) at \(S\) and \(T\). Then \(O_S S U T\) is a kite. Hence the circle \((O_S, U)\) passes through the points \(S\) and \(T\). On the other hand, Dao Thanh Oai has shown that each of the distances from the point \(I\) to the two tangents equals \(2r_A\) [1]. While the distance between \(I\) and the line \(ST\) is also \(2r_A\) [7]. Hence the triangle \(STU\) has incircle of radius \(2r_A\) with center \(I\). Therefore if \(\alpha' = (O_I I), \beta' = (U I)\) and \(\gamma' = (O_U U),\) then the arbelos \((\alpha', \beta', \gamma')\) shares Archimedean circles with \((\alpha, \beta, \gamma)\), and \(STU\) is a poristic triangle of \((\alpha', \beta', \gamma')\) by Corollary 3.2. The axis of \((\alpha', \beta', \gamma')\) is the tangent of \(\gamma\) at the point \(I\), which is parallel to \(ST\) [7]. Let \(a'\) and \(b'\) be the radii of the circles \(\alpha'\) and \(\beta'\), respectively. Then \(a' = g/2\). Solving the equation \(a'b'/\left(a' + b'\right) = r_A\) for \(b'\), we get \(b' = abg/w\). Therefore \(\gamma'\) has radius \(g^3/(2w)\).

5. Another infinitely many sextuplets of Archimedean circles

We consider another infinitely many sextuplets of Archimedean circles of \((\alpha, \beta, \gamma)\), which are obtained from the following simple fact (see Figure 5):

**Proposition 5.1.** If \(D\) is a point lying outside a circle \(C\) and \(M\) is a point lying on one of the tangents of \(C\) from \(D\), then the distance between \(M\) and the line \(DO_C\) equals the radius of \(C\) if and only if \(M\) lies on the circle \(D(O_C)\).

**Proof.** If \(N\) is the foot of perpendicular from \(O_C\) to \(DM\), and \(H\) is the foot of perpendicular from \(M\) to \(DO_C\), then the triangles \(DHM\) and \(DNO_C\) are similar. Hence \(|MH| = |O_C N|\) and \(|DM| = |DO_C|\) are equivalent.
If each of the lines $EF$, $FG$ and $GE$ intersects $AB$, we denote the point of intersections by $U_g$, $U_e$ and $U_f$, respectively for a poristic triangle $EFG$ of $(\alpha, \beta, \gamma)$. If $EF$ and $AB$ are not parallel, let $\delta_g = U_g(O)$. If $EF$ and $AB$ are parallel, let $\delta_g$ be the axis of $(\alpha, \beta, \gamma)$. Similarly $\delta_e$ and $\delta_f$ are defined. By Proposition 5.1, we get the following theorem.

**Theorem 5.2.** The smallest circles touching $AB$ and passing through one of the points of intersection of $EF$ and $\delta_g$ are Archimedean for a poristic triangle $EFG$ of $(\alpha, \beta, \gamma)$. Similar facts are true for $FG$ and $\delta_e$ and for $GE$ and $\delta_f$.

A poristic triangle of $(\alpha, \beta, \gamma)$ gives six Archimedean circles in general by Theorem 5.2. Therefore we also get infinitely many sextuplets of Archimedean circles. Figure 6 shows the sextuplet of Archimedean circles in the case in which the poristic triangle is the base triangle.

### 6. Some special cases

In this section we consider some special cases in which $EFG$ is a special poristic triangle of $(\alpha, \beta, \gamma)$. At the beginning, we consider the case the lines $AB$ and $FG$ being parallel (see Figure 7). If $a \neq b$, let $\delta = \delta_e$ in the case $E = I$ (see Figure 6). The circle $\delta$ is expressed by the equation $(x+2ab/u)^2 + y^2 = (2ab/u)^2$. If $a = b$, we define $\delta$ as the axis. In any case the points of intersection of $\delta$ and $\zeta$ have coordinates $\left(s, \pm r_A \frac{(3a + b)(a + 3b)}{g} \right)$. Hence they lie on the Schoch line and also on the circle $(O_\alpha O_\beta)$ [6]. Let
$Q$ be the point of intersection of $\delta$ and $\gamma$ lying in the region $y > 0$. Its coordinates are [5]:

$$\left(\frac{-2abu}{w}, \frac{2abg}{w}\right).$$

Let $t = \sqrt{w(4 + 4ab)}$. The points of intersection of $\gamma$ and the line $y = -2r_A$ have coordinates

$$(u \pm \frac{t}{g}, -2r_A).$$

**Theorem 6.1.** The following statements are equivalent for a poristic triangle $EFG$ of $(\alpha, \beta, \gamma)$.

(i) The lines $FG$ and $AB$ are parallel.

(ii) The point $E$ coincides with the point $Q$ or its reflection in $AB$.

(iii) $|FU_g| = |OU_g|$ holds.

(iv) $|GU_f| = |OU_f|$ holds.

(v) The foot of perpendicular from $E''$ to $AB$ coincides with the point $O \varepsilon$.

**Proof.** Let us assume (i). We may assume $FG$ lies in the region $y < 0$ and $F$ has coordinates $(u - \frac{t}{g}, -2r_A)$ by (4). Then $FQ$ is expressed by the equation

$$2v^2x + \frac{ug^3 - wt}{2ab}y + gt - uw = 0.$$ 

The distance between $FQ$ and $O$ equals $2r_A$, because we have

$$\frac{(gt - uw)^2}{((2v^2)^2 + ((ug^3 - wt)/(2ab))^2) = 4r^2_A}.$$ 

Hence the line $FQ$ touches $\zeta$. Therefore $QFG$ is a poristic triangle of $(\alpha, \beta, \gamma)$, i.e., $E = Q$. Therefore (i) implies (ii). Since $E \mapsto FG$ is one-to-one correspondence, the converse holds. The part (i) is equivalent to that the distance between $F$ and $AB$ is $2r_A$. This happens only when $|FU_g| = |OU_g|$ by Proposition 5.1. Hence (i) and (iii) are equivalent. Also (i) and (iv) are equivalent. Let $D$ be one of the farthest points on $\varepsilon$ from $AB$. The slope of the line $OQ$ equals $-g/u$ by (3). Also the slope of the line $OD$ equals $\pm r_A/(\mp r_Au/g) = \mp g/u$. Since $E''$ lies on $\varepsilon$ and $EO\varepsilon$, (ii) holds if and
only if \( E'' \) coincides with \( D \) or its reflection in \( AB \). Hence (ii) and (v) are equivalent.

If \( FG \) and \( AB \) are parallel, the point of intersection of \( \delta \) and one of the external common tangents of \( \alpha \) and \( \beta \) lies on \( FG \) by Proposition 5.1.

Let us assume that \( E \) and \( G \) are the points of intersection of the circles \( \gamma \) and \( A(O) \), where \( E \) lies in the region \( y > 0 \) (see Figure 8). Then \( EG \) and the axis are parallel and their distance equals \( 2r_A \) [2], and the triangle \( EFG \) is an isosceles triangle, and \( F \) coincides with \( B \). In this case the points \( E' \) and \( G' \) are the points of intersection of the circles \( \beta \) and \( \zeta \) [9], where the circle \( (G'O) \) is denoted by \( A(2) \) in [9]. The distance between the axis and each of the points of intersection of \( \alpha \) and \( (O_{\alpha}O_{\beta}) \) is \( r_A \) [3]. While the points \( E_m \) and \( G_m \) lies on \( (O_{\alpha}O_{\beta}) \) by (iii) of Theorem 3.1, and their distance from the axis also equals \( r_A \). Therefore \( E_m \) and \( G_m \) are the points of intersections of \( \alpha \) and \( (O_{\alpha}O_{\beta}) \). The arbelos \( (\alpha', \beta', \gamma') \) in Figure 4 is an example of this case.

If \( a = b \), then \( r_A = a/2 \). In this case any poristic triangle \( EFG \) of \( (\alpha, \beta, \gamma) \) is equilateral and the circles \( \zeta \) and \( (O_{\alpha}O_{\beta}) \) coincide (see Figure 9). Also the circle \( \varepsilon \) touches the Archimedean circles with centers \( E_m \) at the point \( E'' \).
